1 Lecture 6: Trapezium rule, Fourier series and Laurent series

This lecture we cover

- 1. Periodic and complex Trapezium rule
- 2. Convergence via Laurent series
- 3. Numerical differentiation via numerical computation of Cauchy integrals

1.1 Periodic Trapezium rule

Quadrature rules are pairs of nodes x_0, \ldots, x_{N-1} and weights w_0, \ldots, w_{N-1} to approximate integrals

$$\int_{a}^{b} f(x)dx \approx \sum_{j=0}^{N-1} w_{j} f(x_{j})$$

In this lecture we construct quadrature rules on complex contours γ to approximate contour integrals.

The trapezium rule gives an easy approximation to integrals. On $[0, 2\pi)$ for periodic $f(\theta)$, we have a simplified form:

Definition (Periodic trapezium rule) The periodic trapezium rule is the approximation

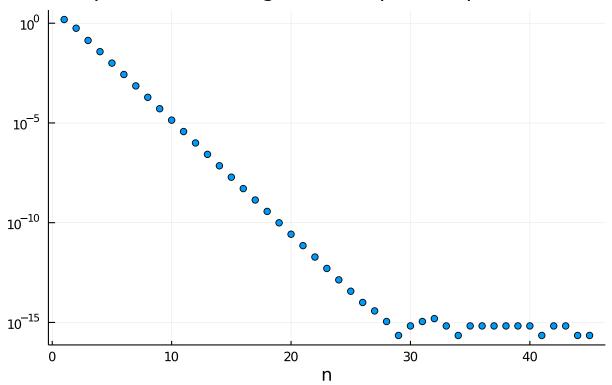

$$\int_0^{2\pi} f(\theta)d\theta \approx Q_N f := \frac{2\pi}{N} \sum_{j=0}^{N-1} f(\theta_k)$$

for
$$\theta_j = \frac{2\pi j}{N}$$
.

The periodic trapezium rule is amazingly accurate for smooth, periodic functions:

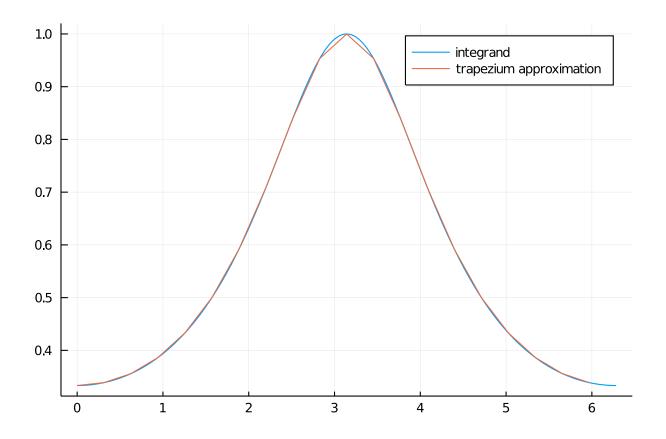

```
using Plots, ApproxFun f = \theta \rightarrow 1/(2 + \cos(\theta)) periodic_rule(N) = 2\pi/N*(0:(N-1)), 2\pi/N*ones(N) errs = [((x, w) = periodic_rule(N); abs(sum(w.*f.(x)) - sum(Fun(f, 0 .. 2\pi)))) for N = 1:45]; scatter(errs.+eps(); yscale=:log10, title="exponential convergence of N-point trapezium rule", legend=false, xlabel="n")
```

exponential convergence of N-point trapezium rule

The accuracy in integration is remarkable as the trapezoidal interpolant does not accurately approximate f: we can see clear differences between the functions here:

```
N=20
(x, w) = periodic_rule(N)
plot(Fun(f, 0 .. 2\pi); label = "integrand")
plot!(x, f.(x); label = "trapezium approximation")
```

1.2 Trapezium rule and Fourier coefficients

Write

$$f(\theta) = \sum_{k=-\infty}^{\infty} \hat{f}_k e^{ik\theta}$$

and assume that the Fourier coefficients are absolutely summable (true if f is smooth enough):

$$\sum_{k=-\infty}^{\infty} |\hat{f}_k| < \infty.$$

Note that geometric series tells us that

$$\frac{1}{2\pi}Q_N e^{ik\theta} = \frac{1}{N} \sum_{j=0}^{N-1} (e^{2\pi i k/N})^j$$

$$= \begin{cases} 1 & \text{if } k = mN \text{ for some integer } m \\ 0 & \text{otherwise} \end{cases}$$

It follows that we can express the Trapezium rule exactly in terms of a sum of Fourier coefficients:

$$\frac{1}{2\pi}Q_N f = \sum_{k=-\infty}^{\infty} \hat{f}_k \frac{1}{2\pi} Q_N e^{ik\theta} = \sum_{k=-\infty}^{\infty} \hat{f}_k \begin{cases} 1 & \text{if } k = mN \text{ for some integer } m \\ 0 & \text{otherwise} \end{cases}$$
$$= \dots + \hat{f}_{-2N} + \hat{f}_{-N} + \hat{f}_0 + \hat{f}_N + \hat{f}_{2N} + \dots$$

In other words, the error in the Trapezium rule is bounded by

$$\left| \int_{0}^{2\pi} f(\theta) d\theta - Q_N f \right| \le 2\pi \sum_{m=1}^{\infty} \left[|\hat{f}_{mN}| + |\hat{f}_{-mN}| \right]$$

if we can show fast decay in the coefficients we can prove the observation that trapezium rule converges fast.

1.3 Decay in Fourier/Laurent coefficients

Now we consider g(z) such that $g(e^{i\theta}) = f(\theta)$, that is, g has the Laurent series

$$g(z) = \sum_{k=-\infty}^{\infty} g_k z^k$$

where $g_k = \hat{f}_k$. Interestingly, analytic properties of g can be used to show decaying properties in Fourier coefficients of f:

Theorem (Decay in Fourier/Laurent coefficients) Suppose g(z) is analytic in a closed annulus $A_{r,R}$ around 0: $A_r(z_0) = \{z : r \leq |z| \leq R\}$. Then for all $k |g_k| \leq M \min\left\{\frac{1}{R^k}, \frac{1}{r^k}\right\}$ where $M = \sup_{z \in A_{r,R}} |g(z)|$.

Proof This is a simple application of the ML lemma: let $k \geq 0$, then

$$|g_k| = \frac{1}{2\pi} \left| \oint_{C_1} \frac{g(\zeta)}{\zeta^{k+1}} d\zeta \right| = \frac{1}{2\pi} \left| \oint_{C_R} \frac{g(\zeta)}{\zeta^{k+1}} d\zeta \right| \le \sup_{\zeta \in C_R} |g(\zeta)| R^{-k} \le M R^{-k}.$$

For k < 0, we deform the contour to C_r .

We thus can show fast convergence of Trapezium rule again using geometric series:

$$\sum_{m=1}^{\infty} \left[|\hat{f}_{mN}| + |\hat{f}_{-mN}| \right] \leq M \sum_{m=1}^{\infty} \left[R^{-mN} + r^{mN} \right] \leq M \left[\frac{R^{-N}}{1 - R^{-N}} + \frac{r^{N}}{1 - r^{N}} \right].$$

Demonstration The Laurent coefficients of $f(\theta) = \frac{1}{2-\cos\theta}$ satisfies for $k \geq 0$

$$|g_k| \le \frac{2}{4 - R - R^{-1}} R^{-k}$$

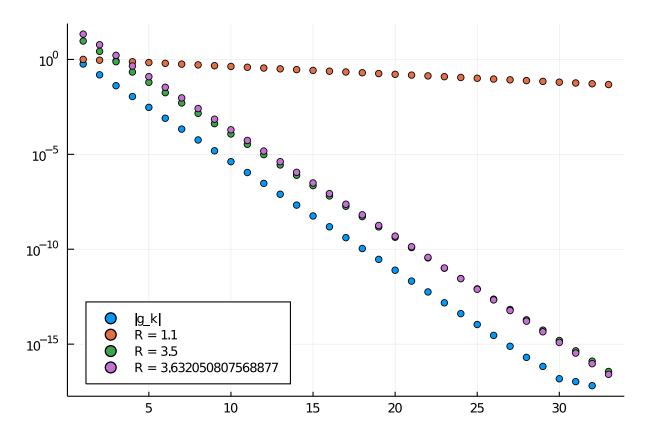

for all $R \le 2 + \sqrt{3}$. The following shows this bound is quite accurate:

```
 g = Fun(\theta \rightarrow 1/(2-cos(\theta)), Laurent(-\pi .. \pi)) 
 g_+ = g.coefficients[1:2:end] 
 scatter(abs.(g_+); yscale=:log10, label="|g_k|", legend=:bottomleft) 
 R = 1.1 
 scatter!(2/(4-R-inv(R))*R.^(-(0:length(g_+))), label = "R = $R") 
 R = 3.5
```

```
scatter!(2/(4-R-inv(R))*R.^{(-(0:length(g_+)))}, label = "R = $R")

R = 2+sqrt(3)-0.1

scatter!(2/(4-R-inv(R))*R.^{(-(0:length(g_+)))}, label = "R = $R")
```

This fast decay in coefficients explains the fast convergence of the trapezium rule.

1.4 Complex Trapezium rule

We can use the map γ that defines a closed contour to construct an approximation to integrals over γ :

Definition (Complex trapezium rule) The *complex trapezium rule* on a contour γ (mapped from $[0, 2\pi)$) is the approximation

$$\oint_{\gamma} f(z)dz \approx \sum_{j=0}^{N-1} w_j f(z_j)$$

for

$$z_j = \gamma(\theta_j)$$
 and $w_j = \frac{2\pi}{N} \gamma'(\theta_j)$

Example (Circle trapezium rule) On a circle $C_r = \{re^{i\theta} : 0 \le \theta < 2\pi\}$, we have

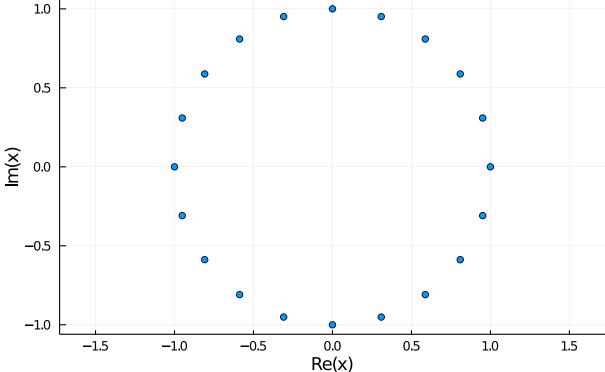

$$\oint_{C_r} f(z)dz \approx \sum_{j=0}^{N-1} w_j f(z_j)$$

for $z_j = r e^{i\theta_j}$ and $w_j = \frac{2\pi i r}{N} e^{i\theta_j}$.

Here we plot the quadrature points:

```
function circle_rule(N, r)
    \theta = periodic_rule(N)[1]
    r*exp.(im*\theta), 2\pi*im*r/N*exp.(im*\theta)
end
\zeta, w = circle_rule(20, 1.0)
scatter(ζ; title="quadrature points", legend=false, ratio=1.0)
```

quadrature points 1.0 0

The Circle trapezium rule is surprisingly accurate for analytic functions, following from the explanation above:

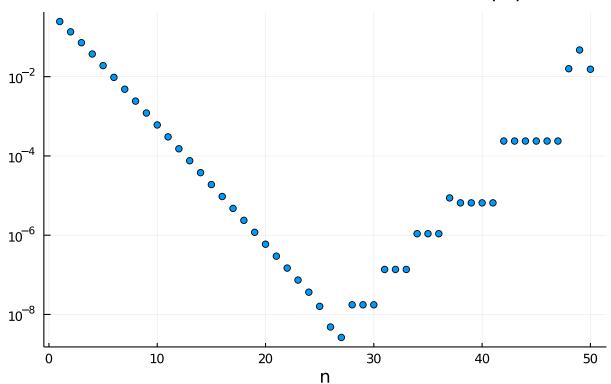

```
\zeta, w = circle_rule(20, 1.0)
f = z \rightarrow cos(z)
z = 0.1 + 0.2im
sum(f.(\zeta)./(\zeta .- z).*w)/(2\pi*im) - f(z)
-9.814371537686384e-14 - 1.3076345561913172e-14im
```

1.5 Application: Numerical differentiation

Calculating high-order derivatives using limits is numerically unstable. Here is a demonstration using finite-differences: making h small does not increase the accuracy after a certain point:

```
using SpecialFunctions
f = z \rightarrow gamma(z)
fp = z -> gamma(z)polygamma(0,z) # exact derivative
x = 1.2
fp_fd = [(h=2.0^{-(-n)}; (f(x+h)-f(x))/h) for n = 1:50]
scatter(abs.(fp_fd .- fp(x)); yscale=:log10, legend=false, title = "error of
finite-difference with h=2^(-n)", xlabel="n")
```

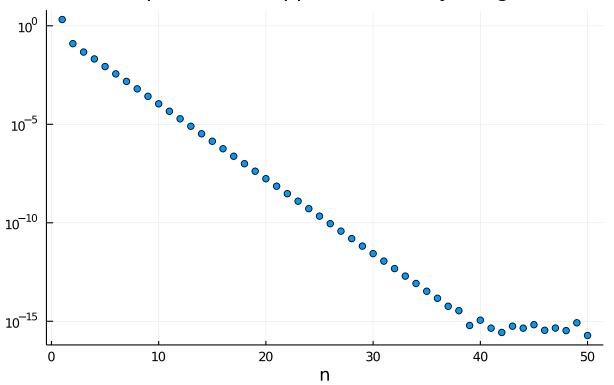

error of finite-difference with h=2^(-n)

But the Cauchy integral formula for derivatives tells us that we can reduce a derivative to a contour integral, which can be computed stably:

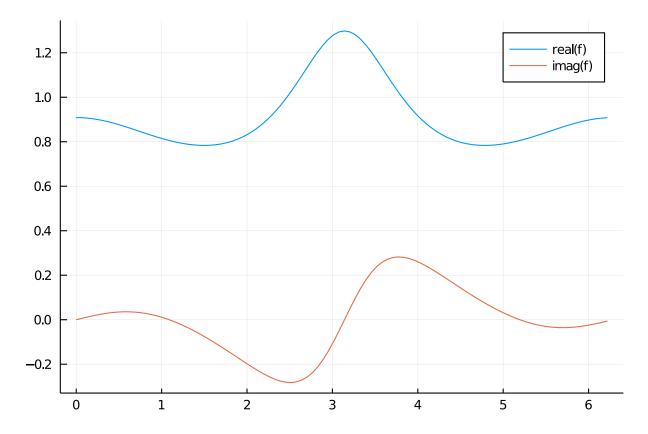

```
 \begin{split} \text{trap\_fp} &= \left[ ((\zeta, \ \text{w}) = \text{circle\_rule}(\text{n}, \ 0.5); \right. \\ &\quad \zeta \ . + = \ \text{x}; \ \# \ circle \ around \ x \\ &\quad \text{sum}(\text{f.}(\zeta)./(\zeta \ . - \ \text{x}).^2 \ . * \text{w})/(2\pi*\text{im})) \ \text{for n=1:50} \right] \\ \text{scatter}(\text{abs.}(\text{trap\_fp} \ . - \ \text{fp.}(\text{x})); \ \text{yscale=:log10}, \\ &\quad \text{title="Error of trapezium rule applied to Cauchy integral formula", xlabel="n", legend=$false$) \\ \end{aligned}
```

Error of trapezium rule applied to Cauchy integral formula

The exponential convergence of the complex trapezium rule is a consequence of $f(\gamma(t))$ being 2π -periodic:

```
\begin{array}{l} \theta = \operatorname{periodic\_rule}(100) [1] \\ \zeta = x .+ 0.5*exp.(im*\theta) \\ \operatorname{plot}(\theta, \operatorname{real.}(f.(\zeta)); \operatorname{label="real}(f)") \\ \operatorname{plot!}(\theta, \operatorname{imag.}(f.(\zeta)); \operatorname{label="imag}(f)") \end{array}
```

Therefore, the integrand of Cauchy's integral formula is periodic and analytic (if f is analytic) on the circular contour.

We can take things further and use this to calculate higher order derivatives, with some care taken for choosing the radius:

```
k=100

r = 1.0k

g = Fun(\zeta \rightarrow \exp(\zeta)/(\zeta - 0.1)^(k+1), Circle(0.1,r))

factorial(1.0k)/(2\pi*im) * sum(g) - exp(0.1)
```

-7.993605777301127e-15 + 3.675487826103639e-16im

Bornemann 2011 investigates this further and optimizes the radius.

Example (Ellipse trapezium rule) On an ellipse $\{a\cos\theta+b\mathrm{i}\sin\theta:0\leq\theta<2\pi\}$ we have

$$\oint_{\gamma} f(z)dz \approx \sum_{j=0}^{N-1} w_j f(z_j)$$

for $z_j = a\cos\theta_j + bi\sin\theta_j$ and $w_j = \frac{2\pi}{N}(-a\sin\theta_j + ib\cos\theta_j)$.

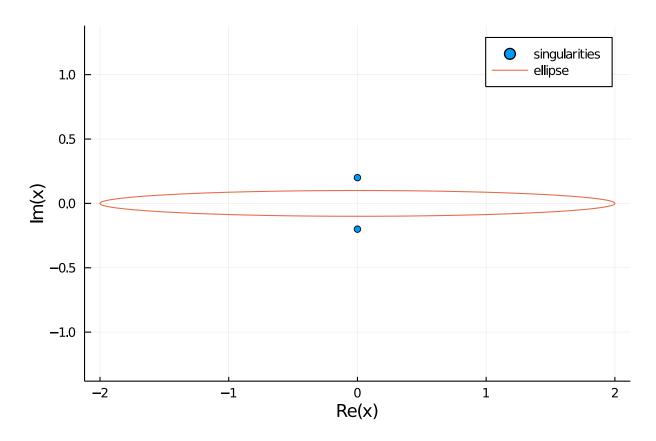

We can use the ellipse trapezium rule in place of the circle trapezium rule and still achieve accurate results. This gives us flexibility in avoiding singularities. Consider

$$f(z) = 1/(25z^2 + 1)$$

which has poles at $\pm i/5$. Using an ellipse allows us to design a contour that avoids these singularities:

```
scatter([1/5im,-1/5im]; label="singularities") \theta = \text{range}(0; \text{stop}=2\pi, \text{length}=2000)
```

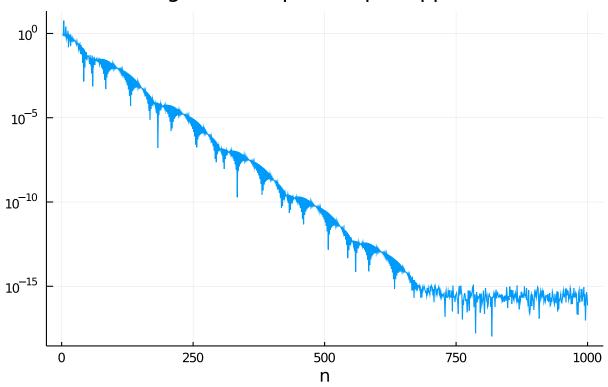

```
a = 2; b= 0.1 plot! (a * cos.(\theta) + im*b * sin.(\theta); label="ellipse", ratio = 1.0)
```

Thus we can still use Cauchy's integral formula:

```
 \begin{array}{l} x = 0.1 \\ f = z \rightarrow 1/(25z^2 + 1) \\ function \ ellipse\_rule(n, a, b) \\ \theta = periodic\_rule(n)[1] \\ a*cos.(\theta) + b*im*sin.(\theta), 2\pi/n*(-a*sin.(\theta) + im*b*cos.(\theta)) \\ end \\ f\_ellipse = [((z, w) = ellipse\_rule(n, a, b); sum(f.(z)./(z.-x).*w)/(2\pi*im)) \ for \\ n=1:1000] \\ plot(abs.(f\_ellipse .- f(x)); yscale=:log10, title="convergence of n-point ellipse approximation", legend=false, xlabel="n") \\ \end{array}
```

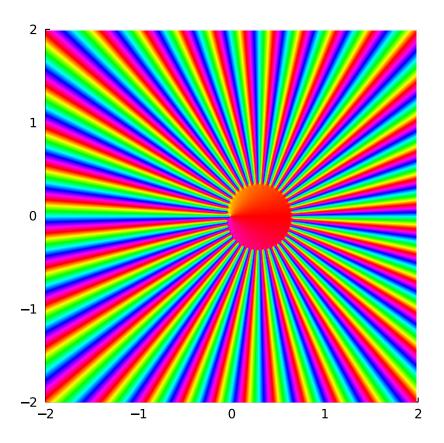

convergence of n-point ellipse approximation

1.6 Taylor series versus Cauchy integral formula

The Taylor series gives a polynomial approximation to f. The Cauchy's integral formula discretisation gives a rational approximation, which is more adaptable and does not require knowing the derivatives of f:

```
using ComplexPhasePortrait
f = z -> sqrt(z)
function sqrt_n(n,z,z_0)
    ret = sqrt(z_0)
    c = 0.5/ret*(z-z_0)
    for k=1:n
        ret += c
        c *= -(2k-1)/(2*(k+1)*z_0)*(z-z_0)
    end
    ret
end
z_0 = 0.3
n = 40
phaseplot(-2..2, -2..2, z -> sqrt_n.(n,z,z_0))
```

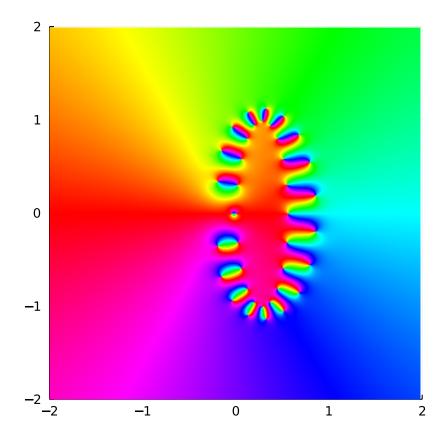

Here we see that the approximation is valid on the expected ellipse:

```
(\zeta, w) = ellipse\_rule(20, 0.28, 1.0);

\zeta = \zeta + 0.3;

f_c = z \rightarrow sum(f.(\zeta)./(\zeta.-z).*w)/(2\pi*im)

phaseplot(-2..2, -2 .. 2, f_c)
```

```
(\zeta, w) = ellipse\_rule(1000, 0.28, 1.0);

\zeta := \zeta .+ 0.3;

f_c = z -> sum(f.(\zeta)./(\zeta.-z).*w)/(2\pi*im)

f_c(0.5) - sqrt(0.5)
```
